Abstract. A number of formal proposals to manage aliasing in Java-like programming languages have been advanced over the last five years. Unfortunately, it is not clear how practical these proposals are, that is, how well they relate to the kinds of programs currently written in those languages. We have analysed heap dumps from a corpus of Java programs to identify their implicit aliasing structures, including object ownership, confinement, and uniqueness. Understanding the kinds of aliasing present in programs should help us to design formalisms to make explicit the kinds of aliasing implicit in object-oriented programs.

1 Introduction

There has been much recent research on managing aliasing in object-oriented programming languages through uniqueness, ownership, and confinement [2, 7, 8, 3, 4, 1, 5]. Unfortunately, it is not clear how applicable many of these approaches will be: that is, how well they can describe the kinds of aliasing used by programmers in practice. While there should be more to theories of object-oriented program design than irrelevant rhetoric, there is surprisingly little solid evidence that programmers concern themselves with encapsulation, or adopt encapsulation disciplines in the programs they actually write.

In this paper we take an empirical approach to evaluating aliasing in object-oriented systems. By analysing snapshots of a corpus of running Java programs' heaps, we search for evidence of object uniqueness, ownership, and confinement. We hope that our results will enable researchers to verify their results and find new directions in the formal exploration of aliasing.

2 Rabbit: Analysing Object Graphs

To access the object graph of a running Java program we used the HPROF library that comes with Sun's JDK 1.2 or higher, HPROF uses JVMPI [11] to obtain a snapshot of the entire heap of the running Java program, and then outputs the heap into a binary file or converts the data into readable text output. The binary heap dump can be parsed using a tool created by Bill Foote of Sun Microsystems called HAT (Heap Analysis Tool) [10]. HAT is written in Java and can be used by another program that wishes to have easy access to the object graph from the heap.

Our tool is called Rabbit, and uses the HAT as a library to get access to the object graph data. Rabbit then proceeds to construct an ownership forest using the heap root set

objects as roots and makes the forest into a single ownership tree by adding a global root above all else. Having obtained the data it requires, Rabbit runs a number of experiments to analyse the object graph and the ownership tree.

An important point about Rabbit is that it empirically evaluates encapsulation based on a heap snapshot of a running Java program, as opposed to the static source code or dynamic behaviour traces. We chose this method because we aim to analyse the encapsulation latent within a corpus of programs, rather than benchmark a particular algorithm or alias protection scheme. Compared to static confinement checkers like Kacheck/J [5] our approach is optimistic: an object may be identified as unique, confined, or otherwise encapsulated, depending on the state of the object graph at the instant a heap dump is taken. Thus, our results overestimate the encapsulation data: an object which is encapsulated at one instant (or in one program run) may be aliased the next instant, or in the next run. On the other hand, more conservative approaches such as Kacheck/J cannot identify objects which are effectively encapsulated in practice unless they can prove the objects will be encapsulated across all potential program executions, most of which will never occur.

We have calculated encapsulation metrics across 52 dumps obtained from a corpus of around 30 programs — half of which were taken from the Purdue Benchmark Suite, the others are freely available over the Internet. The dumps for large programs were taken at different stages: *initial*, when the program is initialized but hasn't been used yet, *normal*, when the program was used in a normal way, and *heavy*, when the program was driven to use as much memory as possible. To determine the sensitivity of our analysis to the precise instants when dumps were taken, we made several additional dumps for some of the large programs in our corpus. So far, no discrepancies have been detected in this way.

3 Results

The results obtained using the Rabbit are described here and are presented in the two tables in the Appendices A and B. The first table gives most of the metrics, while the second one specifically concentrates on class confinement.

For each heap dump, we give the number of objects in the object graph (**NO**), the number of unique roots in the Java heap root set (**NUR**), and the number of objects accessible by reference traversal (**ART**) from the root set (other objects are presumed to be uncollected garbage). These numbers give an idea of the size of the program under consideration. We found that a typical Java program in the corpus at had around 60000 objects allocated on the heap, about 1800 of these were part of the Garbage Collector's root set (this includes static and global variables, metaobjects, and references from the Java stack) and 3000 (around 5% or less) were garbage, i.e. not accessible from the root set.

Uniqueness Uniqueness is the most basic type of aliasing control: a unique object is encapsulated within its sole referring object [2].

We analysed the object graphs to determine the number of non-unique objects, in particular, the percentage of objects with more than one incoming reference (**PMOIR**).

We found that on average only 13% of all objects had more than one object pointing at them, or in other words had an alias. This means that the number of aliases in the systems we looked at was not too high. By comparing different stages of the program run, we found that the percentage of aliased objects in the system often increased. For example, *Kacheck/J* rises from 3.01% of aliased objects during the initial stage to 14.09% of objects being aliased in the heavy load stage. Given that the majority of objects are not aliased, we consider that it make sense for formal techniques to support uniqueness, however, there are enough aliased objects that uniqueness alone will be insufficient for managing aliasing within an object-oriented programming style.

Object Ownership Object ownership is in essence a generalisation of uniqueness [9] that underlies many more sophisticated alias management schemes [8, 4, 3, 7]. An object *a* owns another object *b* if all the paths from the root *r* to the object *b* go through *a*. In this case *b* is called the *owner* of *a*. The implication of ownership is that no object outside the owner *b* is allowed to have a reference to *a*. We posit a global root *r* through which all the objects in the root set of the current heap snapshot can be accessed. Ownership allows us to structure an object graph into an implicit ownership tree.

Our primary metric of object ownership is the average depth (**AD**) of an object in the ownership tree, that is, the average numbers of levels of encapsulation around any object. In most programs in the corpus, this was around 5 or 6; however some large programs had substantially larger values (e.g. 817.25 for BlueJ under heavy load).

Given these figures, we hypothesised that large data structures such as linked lists could have a very significant effect when calculating the average depth of the node in the ownership tree: the average depth of a list node would be half the length of the list. To address this issue, we decided to fold up the reference paths by counting chains of objects of same class (e.g. `LinkedList$Node`) as having the length of 1. This gave us a less biased account, with the average depth after folding (**ADF**) being around 5.47 as opposed to 42.77 across all programs, with the large outlying depths being greatly reduced (e.g. a simple linked list test program has AD 142.37, ADF 4.21). The resulting ownership metric does demonstrate, however, that there is a significant amount of object-based encapsulation in Java programs.

We also calculated the average ownership tree depth per class; this gave us a finer-grained picture of object ownership but the results cannot be presented here for space reasons. As an example of the average depth from root per class consider `java.lang.Hashtable`. Since most `java.util.Hashtable` instances should own (approximately one) `java.util.Hashtable$Entry[]` array instance, we would expect the average depth of the latter to be one greater than the former. The following sample of the Rabbit output for **BlueJ** confirms this hypothesis, and also implies the actual hashtable entries are contained within the entry array.

```
Class java.util.Hashtable has 279 instances and on
average each instance node is 3.96 deep.
[snip]
Class java.util.Hashtable$Entry[]; has 297 instances
and on average each instance node is 4.90 deep.
[snip]
```

Class `java.util.Hashtable$Entry` has 3990 instances and on average each instance node is 5.37 deep.

Confinement The third aspect of encapsulation we analyse is object confinement which is an instantaneous approach to class confinement [1, 5]. If all the referrers to an object are in the same package as the object’s class, we call the object strongly confined. If all the referrers are in the same top level package, we call the object weakly confined, this is similar to the idea of hierarchical packages in [1, 5]. If there are referrers from a different package, we call it not confined. For example, if `java.util.Vector` object is pointed at by `hat.model.Snapshot` object, then it is not confined. If all the referrers of `java.util.Vector` are members of `java.*` but not necessarily of `java.util.*` then it is weakly confined.

We have calculated a number of confinement metrics over the object graphs of the programs in our corpus, by considering all objects that refer to each object. We take an abductive view of class confinement: if the class is deduced to be confined to its package at all times during the program run [5], then all the instances of it should be confined from our point of view.

Our measurements have shown that around 46% of the objects were not confined (**NC**), 21% were weakly confined (**WC**), and 33% were strongly confined (**SC**). At first glance, these numbers are roughly what static analysis by Grothoff, Palsberg, and Vitek [5] leads us to expect, even though we are looking from a different perspective.

We further analysed confinement on a per-class basis, rather than per-object. The second table (Appendix B) gives the class confinement distribution. The first column, called 0%, lists the number of classes that have no instances that are strongly confined, and further columns list the number of classes that have a number of instances being strongly confined falling into a corresponding decile. The column named 100% counts those that have all their instances strongly confined. The last column is the Total Number of Classes (**TNC**).

One interesting feature of this table is that the 0% and 100% columns have by far the largest values: all the instances of a class tend to have the same confinement. We had hypothesised that there may be a significant fraction of the instances of some classes which were “almost” confined (90%), but this did not appear to be the case.

We can see that the vast majority of classes with instances present in our heap snapshot are not confined (88.48%). After comparing our results with the data obtained using the static control flow analysis by Grothoff, Palsberg, and Vitek [5] we noticed that the majority of classes that their tool detected as being confined at all times have not been instantiated in any of our heap snapshots. Those that were instantiated, we confirmed were confined from our perspective too.

Multiple Dumps The results presented here were based on the encapsulation information contained in a single snapshot. This does not allow us to trace the owners throughout the execution or across a sequence of heap dumps of the same program run.

For several large dumps in our corpus we analysed a sequence of heap snapshots taken during the same run of the program. Although our tool could not trace the objects from snapshot to snapshot, there were no drastic changes in the metrics we calculated.

One of our goals for the future is the ability to monitor the development of the ownership structure during the program run to make sure that we are getting an appropriate reflection of the encapsulation picture.

4 Further Work

We are continuing to analyse a number of encapsulation metrics not presented here, including Number of Objects Owned (on Average, Minimum, and Maximum) *per Class*, Average Depth from Root *per Class*, Percentage of Strongly Confined Instances *per Class*, Distribution of the Number of Instances, Average Number of Incoming References, Percentage with Only One Incoming Reference, and the Maximum Depth of the Ownership Tree.

At the moment, we are working on the next version of the tool that will allow the experiments to be expressed as queries (in a manner similar to the Query-Based Debuggers [6]) to make the process of examining the heap structure as easy and as flexible as possible.

5 Conclusions

We have presented the results related to the ownership and confinement obtained using Rabbit, a tool that analyses snapshots of a Java program heap. We measured 52 heap snapshots of a corpus of over 30 programs, from test programs to larger systems with over 350,000 objects. We found that only around twelve percent of objects (ranging from 5-20 percent) had more than one incoming reference; that objects were on average five layers deep within an object ownership hierarchy; and that around one third of all objects were strongly confined according to our instantaneous confinement definition.

We consider that these results indicate that object-oriented programs do in fact exhibit symptoms of encapsulation in practice, and that formal models of uniqueness, ownership, and confinement, can usefully describe the aliasing structures of object-oriented programs.

The Rabbit tool and our corpus of heap dumps is available at: <http://www.mcs.vuw.ac.nz/~alex/rabbit/>. This work is supported by the Royal Society of New Zealand Marsden Fund.
