# Martin-Löf randomness-reminder

- ▶ A **c.e. open set** is one of the form  $\bigcup_i (q_i, r_i)$  where  $\{q_i : i \in \omega\}$  and  $\{r_i : i \in \omega\}$  are c.e..  $U = \{[\sigma] : \sigma \in W\}$ . Here  $[\sigma] = \{\sigma\alpha \mid \alpha \in 2^\omega\}$ , and has measure  $\mu([\sigma]) = 2^{-|\sigma|}$ .
- ▶ A **Martin-Löf test** is a uniformly c.e. sequence  $U_1, U_2, \dots$  of c.e. open sets s.t.

$$\forall i (\mu(U_i) \leq 2^{-i}).$$

(Computationally shrinking to measure 0)

## Definition

$\alpha$  is **Martin-Löf random** if for every Martin-Löf test,

$$\alpha \notin \bigcap_{i>0} U_i.$$

## The martingale view

- ▶ Back to von Mises 1919. Think about predicting the next bit of a sequence. Then you bet on the outcome. You should not win!
- ▶ (Levy) A **martingale** is a function  $f : 2^{<\omega} \mapsto \mathbb{R}^+ \cup \{0\}$  such that for all  $\sigma$ ,

$$f(\sigma) = \frac{f(\sigma 0) + f(\sigma 1)}{2}.$$

- ▶ the martingale *succeeds* on a real  $\alpha$ , if  $\limsup_n F(\alpha \upharpoonright n) \rightarrow \infty$ .

- ▶ Think of betting on sequence where you know that every 2nd bit was 1. Then every second bit you could double your stake. This martingale exhibits exponential growth and that can be used to characterize computable reals.
- ▶ Ville proved that null sets correspond to success sets for martingales. They were used extensively by Doob in the study of stochastic processes.

- ▶ A **supermartingale** is a function  $f : 2^{<\omega} \mapsto \mathbb{R}^+ \cup \{0\}$  such that for all  $\sigma$ ,

$$f(\sigma) \geq \frac{f(\sigma 0) + f(\sigma 1)}{2}.$$

- ▶ Schnorr showed that Martin-Löf randomness corresponded to effective (super-)martingales failing to succeed.
- ▶  $f$  as being **effective** or **computably enumerable** if  $f(\sigma)$  is a left-c.e. real, and at every stage we have effective approximations to  $f$  in the sense that  $f(\sigma) = \lim_s f_s(\sigma)$ , with  $f_s(\sigma)$  a computable increasing sequence of rationals.

## Theorem (Schnorr)

*A is Martin-Löf random iff no effective martingale succeeds on it.*

► Also lead to variations on randomness:

1. Schnorr randomness ( $\mu(U_n) = 2^{-n}$ ),
2. computable randomness (only computable martingales),
3. Kurtz randomness  $U_n$  is a canonical clopen set-or  $A \in V_n$  for all open  $V_n$  of measure 1.

# Integer Valued Randoms

- ▶ Many notions of randomness.... I know a good book or two.
- ▶ If you actually go to a casino, and try to bet  $\mathbb{Y}_{\frac{1}{10000000}}$ , they will not accept the bet.
- ▶ What about if you ask that bets should be in multiples of certain discrete amounts. The canonical example being  $\$0, 1, 2, 3, \dots$
- ▶ By multiplying, we can regard the the values as integers in the martingale.

## Definition (Beinvenu, Stephan, Teutsch)

$X$  is IVR iff no computable integer valued martingale succeeds on  $X$ .

- ▶ For a set  $F$ , can define  $F$ -valued, if it only takes values from  $F$ .
- ▶ We can similarly define single valued if the set of possible bets is a singleton, (either no bet or)  $a$ .
- ▶ Similarly finitely valued.

## Theorem (Bienvenu, Stephan, Teutsch)

1. *Computably random implies IVR implies FVR implies SVR*
2. *Kurtz random implies SVR*
3. *FVR implies bi-immune.*

- ▶ As we already know, computable implies Schnorr implies Kurtz (with no reversals)
- ▶ Schnorr implies law of large numbers.

## Theorem ([Bienvenu, Stephan, Teutsch])

*No other implications hold.*

# The essential difference

- ▶ There are **finitary** strategies to defeat IV martingales.
- ▶ If  $m$  bets on an outcome, say  $\sigma_1$  in favour of  $\sigma_0$ , then if we choose  $\sigma_0$  he **must lose at least \$1**.

## Definition (Actually a Theorem-Jockusch and Posner)

$A$  is called  **$n$ -generic** if  $A$  meets or avoids each  $\Sigma_n^0$  set  $S$  of strings. That is either

- ▶  $\exists \sigma \in S(\sigma \prec A)$ , or
- ▶  $\exists \sigma \prec A \forall \tau \in S(\sigma \not\prec \tau)$ .

(Kurtz)  $B$  is **weakly  $n$ -generic** if  $A$  meets all dense  $S$ 's.

## Theorem (BST)

*If  $A$  is weakly 2-generic then  $A$  is IVR. Hence IVR's are co-meager.*

However:

## Theorem (BST)

*There is a 1-generic which is **not** IRV.*

## Corollary

*IVR does not imply Schnorr randomness.*

## Recent events

- ▶ Many of these arguments worked also on martingales with a “minimum nonzero bet”.
- ▶ It was a question of Bienvenu, Stephan and Teutsch whether this was the same as IRV, ie computable martingales which only bet on  $\{0\} \cup [1, \infty]$ .
- ▶ Ron Peretz (LSE), and Hoi and Stephan showed that the answer is “no” for many variations of this question.
- ▶ Also showed  $\mathbb{Q} \cap [0, \infty)$  is stronger than  $\mathbb{Z}^{\geq 0}$ .

## Other strangenesses of IVR's

- ▶ One of the classic methods for martingales is called the **savings trick**.
- ▶ This says, given a martingale  $m$  convert it into a new one  $n$  by; after you win a dollar, put it in the bank, and bet the **same proportion** as  $m$ , till you make another dollar.
- ▶ The result has the property that it is (up to  $\pm 1$ ) **nondecreasing**.

### Theorem (Teutsch)

*There is an  $X$  which is not IRV but is IVR for martingales with the savings property.*

- ▶ Of course, the reason is that **proportions** are not available. His method exploits this.

### Theorem (Chalcraft, Dougherty, Freiling, Teutsch)

*If  $B$  and  $A$  are finite integer value sets, then every  $B$ -IVR is  $A$ -IVR iff there is a  $c$  with  $B \supseteq c \cdot A$  some  $c \in \mathbb{Q}$ .*

- ▶ The proof of the easy direction is that if  $B \supseteq c \cdot A$  then any bet  $A$  makes  $B$  can simply make a multiple of, so “essentially” the same bet up to scaling.
- ▶ The hard direction observes that if  $B \not\supseteq c \cdot A$ , then we construct a real that  $S_A$  succeeds on and  $B$  does not.
- ▶  $S_A$ 's strategy is to always bet on 0, and cycle through its values,  $\{a_1, \dots, a_n\}$
- ▶ We can always assume that  $B$  bets on 0 else we make easy progress.
- ▶ We compare  $\frac{S_A\text{'s capital}}{M_B\text{'s capital}}$  with  $\frac{S_A\text{'s bet}}{M_B\text{'s bet}}$ .
- ▶ If the first  $\geq$  second bet 0 **S wins more proportionally to its capital**, if the second exceeds first bet 1 **M loses more proportionally to its capital**.
- ▶ It can be proven that  $\frac{S_A\text{'s capital}}{M_B\text{'s capital}} \rightarrow \infty$  unless it has a limit  $C$ , and then  $c = \frac{1}{C}$  is the multiple

- ▶ **Not** known if this is true for  $A, B$  computable and infinite.
- ▶ (Downey and Melnikov) **Can** have same randoms for **some**  $A$  and  $B$ .

## Our questions

- ▶ What kinds degrees have/bound IVR's?
- ▶ Are these degree notions?
- ▶ What kinds of genericity might align itself to IVR's. We know weak 2- is enough, and 1- is not enough.
- ▶ Does it matter for left c.e. reals?
- ▶ What about partial IVR's? That is in a casino I won't tell you what I would bet in advance. So consider the definition with  $m$ 's **partial computable**.
- ▶ What about c.e. degrees? Do they relate to any known degree class?

## Multiply generic reals

- ▶ A new genericity notion. Recall that a  $\Sigma_1^0$  set is the range of a computable  $f$ . What about if this is  $\omega$ -c.a., and with the property that it has an approximation  $g$  such that for all  $n$ ,  $g(n, s) \preceq g(n, s + 1)$ . We call this **proper**.
- ▶ Recall that an **order** is a computable function  $h$  with  $h(n + 1) \geq h(n)$  and  $h(n) \rightarrow \infty$ .
- ▶ For an order  $h$ , say that  $f$  is  **$h$ -c.a.** if the approximation has  $g(n, s + 1) \neq g(n, s)$  at most  $h(n)$  many times.

### Definition

Let  $h$  be an order. We say that  $A$  is  $h$ -multiply generic if  $A$  meets or avoids all sets  $S$  which are the ranges of proper  $h$ -c.a. functions. Similarly for weakly and dense sets.

- ▶ Evidently for any computable  $h$ ,  $\emptyset'$  can compute an  $h$ -multiply generic.

## Theorem

*If  $h$  and  $h'$  are orders and  $G$  is  $h$ -(weakly) multiply generic, then it is also  $h'$ -(weakly) multiply generic. Thus  $A$  is multiply generic iff  $A$  is  $h$ -multiply generic for some  $h$ .*

## Lemma

*If  $G$  is weakly multiply generic then it is also IVR. The converse is not true since MLR's are not weakly 1-generic.*

The proof is modelled on that by Bienvenu et. al. noting that all that is needed is the weak multiple genericity.

# Array noncomputable degrees

## Definition (Downey, Joskusch, Stob)

A degree  $\mathbf{a}$  is called **array noncomputable** iff for all functions  $f \leq_{wtt} \emptyset'$  there is a function  $g$  computable from  $\mathbf{a}$  such that

$$\exists^\infty x (g(x) > f(x)).$$

- ▶ Looks like “non- $\text{low}_2$ .”
- ▶ Indeed many  $\text{nonlow}_2$  constructions can be run with only the above. For example, every anc degree bounds a generic.
- ▶ The c.e. ones are of special interest.

## A ubiquitous class

- ▶ c.e. and degree are those that:
- ▶ (Kummer) Contain c.e. sets of infinitely often maximal Kolmogorov complexity  $C(A \upharpoonright n) = 2 \log n$ .
- ▶ Have effective packing dimension 1 (Downey and Greenberg)
- ▶ Compute left c.e. reals  $\alpha$  (halting probabilities) and  $B <_T \alpha$  such that if  $V$  is a presentation of  $\alpha$  (that is  $V$  is prefix free, c.e. and  $\alpha = \mu(V)$ ), then  $V \leq_T B$ . (Downey and Greenberg)
- ▶ (Downey, Jockusch, and Stob) bound disjoint c.e. sets  $A$  and  $B$  such that every separating set for  $A$  and  $B$  computes the halting problem
- ▶ have strong minimal covers (Ishmukhametov).
- ▶ (Cholak, Coles, Downey, Herrmann) The array noncomputable c.e. degrees form an invariant class for the lattice of  $\Pi_1^0$  classes via the thin perfect classes
- ▶ (Downey and Greenberg) Compute c.e. sets  $A \equiv_T B$  and  $C <_T A$  such that the inf of the wtt degrees of  $A$  and  $B$  is  $C$ .

## Theorem

*Every array noncomputable degree  $\mathbf{a}$  bounds a weakly multiply generic and hence a IVR.*

The proof models itself on the classical one that each c.e. degree bounds a 1-generic.

# What about multiply generics?

- ▶ These need another concept.

## Definition (Downey, Greenberg, Weber)

We say that a c.e. degree  $\mathbf{a}$  is **totally  $\omega$ -c.e.** iff for all functions  $g \leq_T \mathbf{a}$ ,  $g$  is  $\omega$ -c.e.. That is, there is a computable approximation  $g(x) = \lim_s g(x, s)$ , and a computable function  $h$ , such that for all  $x$ ,

$$|\{s : g(x, s) \neq g(x, s + 1)\}| < h(x).$$

- ▶ array computability is a uniform version of this notion where  $h$  can be chosen independent of  $g$ .
- ▶ Every array computable degree (and hence every contiguous degree) is totally  $\omega$ -c.e..
- ▶ Can extend to **computable ordinals** (Downey and Greenberg).
- ▶ These degrees are **definable** in the c.e. degrees (DGW), and (Downey and Ng) correspond to the degree containing **computably finitely random** reals.

## Theorem

- ▶ *Every not totally  $\omega$ -c.a. c.e. set computes a multiply generic set.*
- ▶ *Every not totally  $\omega^2$ -c.a. set computes a multiply generic set.*

- ▶ The left c.e. case.
- ▶ Notably, there are left c.e. computably random reals (and hence IVR) in each high c.e. degree.

## Theorem

*If  $X$  is left c.e. and IVR then  $X$  is of high degree.*

- ▶ We want to construct a procedure  $\Gamma^X(e, s)$  such that  $\lim_s \Gamma^X(e, s) = \text{Tot}(e)$ .
- ▶ The cycle for  $(x, s)$  is to use the smallest new place in the approximation of  $X_s$  with  $X_s(n) = 1$ . For  $s' \geq s$  we set  $\Gamma^X(e, s')[t'] = 0$  until  $\text{Tot}(e)$  looks more total as more arguments converge. We have inductively defined a partial computable  $m = m_e$  up to strings of length  $s$ .
- ▶ If  $\text{Tot}(e)$  looks more total at stage  $t > s$  we play  $m$  conservatively except on  $n(t)$  playing to win \$1 there on the 1 outcome.
- ▶ The key is that almost always he **must** move away, and he cannot play where we have lost.

## Theorem

- ▶ *There are IVR's that are not partial IVR.*
- ▶ *There are partial IVR's that are not partial computably random.*

## Theorem

*If  $S$  is  $CEA(\emptyset')$ , then there is an IVR  $A$  of c.e. degree such that  $A' \equiv_T S$ .*

The proof uses “big uses” to create space.

## But on the other hand

### Theorem

*There are array noncomputable c.e. degrees containing **no** IVR's.*

In fact:

### Theorem

*There is a  $high_2$  c.e. degree containing **no** IVR's.*

Thank You
